Abstract—This paper presents a control strategy that allows a group of mobile robots to position themselves to optimize the measurement of sensory information in the environment. The robots use sensed information to estimate a function indicating the relative importance of different areas in the environment. Their estimate is then used to drive the network to a desirable placement configuration using a computationally simple decentralized control law. We formulate the problem, provide a practical control solution, and present the results of numerical simulations. We then discuss experiments carried out on a swarm of mobile robots.

I. INTRODUCTION

We consider the problem of controlling networked groups of mobile robots in a decentralized fashion. Such mobile sensor networks promise the ability to collect information over distributed, large-scale domains with minimum infrastructure maintenance. This technology will enable scientific studies on geological and ecological scales previously beyond practical reach, and provide tools for a host of security and surveillance applications.

In this paper, we present a decentralized control law for producing increased robot density in areas of high importance and decreased density in areas of low importance. Specifically, we consider a group of robots that is dispatched over a bounded region of interest. The group’s task is to sample a sensory function over the region. The sensory function is a scalar function unknown to the robots that indicates the relative importance of different areas in the region. Our solution composes an approximation of this function from sensory measurements. A decentralize control law then uses this approximation, as well as neighbor positions, to drive the robots to a configuration such that the sampling of the sensory function is near-optimal. The control strategy was implemented in numerical simulation and on a swarm of mobile robots.

A. Relationship to Prior Work

This problem belongs to the general category of coverage problems. Various strategies have been introduced for controlling coverage with networked mobile robots, and our work builds on several important results in this category. In [9], mobile sensing agents are controlled using potential functions for inter-agent interactions. Stability results are derived, but the optimality of the network configuration is not addressed. Similarly, in [2] an algorithm is proposed that allows for agents to concentrate in areas of high event density while maintaining area coverage constraints. The algorithm is proved to maintain sensor coverage for a limited case without addressing optimality. Most relevant to this paper is a body of results reported in [1], [5], and [4]. In this work decentralized control laws are derived for positioning mobile sensor networks optimally with respect to a known event probability density. This approach is advantageous because it guarantees that the network (locally) minimizes a cost function relevant to the coverage problem. However, the control strategy requires that each agent have a complete foreknowledge of the event probability density, thus it is not reactive to the sensed environment.

Our control strategy is an extension to the one reported in [5]. We re-interpret the problem in a non-probabilistic framework, and derive a local control law which requires that each agent can measure the value and gradient of a sensory function. In contrast to [5], the robots do not require foreknowledge of this function. Instead, the robots approximate the function from sensor measurements while maintaining or seeking a near-optimal sensing configuration. Also in contrast to [5], our function approximation yields a control law with a computationally efficient closed form. This eliminates the need for numerical integration of an arbitrary function over a polygonal domain at every time step. The control law results in near-optimal, as opposed to optimal, performance, though the difference is shown to be negligible in practice. We demonstrate the effectiveness and computational simplicity of
the algorithm in numerical simulations and in experiments on swarms of 40-50 robots (see Figure 1).

II. PROBLEM FORMULATION

In this section, we build a function representing the sensing cost associated with a network configuration. A network is said to have optimal coverage if it minimizes this cost function over the region of interest. Following standard results in the field [5], we show that all configurations of a certain type, namely centroidal Voronoi configurations, correspond to local minima of the cost function.

The sensor network consists of a group of identical robots, each with some degree of mobility and the capacity for measuring a sensory function from the environment. The sensory function indicates the relative importance of different areas in the environment. It may be a quantity that is sensed directly, such as temperature, or it may demand more elaborate processing of sensory data, such as would be required to detect the concentration of a chemical, or the intensity of sound of a particular frequency. In addition, we assume that a robot can measure the positions of its Voronoi neighbors relative to itself, and that it can detect the boundaries of the region of interest.

We review the formalism introduced in [5] to rigorously model the scenario described above.

Let there be \( n \) robots in a known, convex polytope \( Q \subset \mathbb{R}^N \). An arbitrary point in \( Q \) is denoted \( q \), the position of the \( i^{th} \) robot is denoted \( p_i \), and the set of all robot positions is denoted \( P = \{ p_1, \ldots, p_n \} \). Let \( \mathcal{W} = \{ W_1, \ldots, W_n \} \) be a partition of \( Q \) such that each robot \( p_i \) lies within each region \( W_i \). Define the sensory function, \( \phi(q) : Q \rightarrow \mathbb{R}_+ \), as a scalar function with continuous first derivatives over \( Q \). The function \( \phi(q) \) is not known by the robots in the network.

Let the unreliability of the sensor measurement be defined by a function \( f(x) \) which is strictly increasing. Specifically, \( f(\|q-p_i\|) \) describes how unreliable is the measurement of the information at \( q \) by a sensor at \( p_i \) (henceforth, \( \| \cdot \| \) is used to denote the \( \ell^2 \)-norm). This form of \( f(x) \) is physically appealing since it is reasonable that sensing will become more unreliable farther from the sensor.

We can formulate the cost incurred by one robot sensing over one region \( W_i \) as

\[
h_i(p_i, W_i) = \int_{W_i} f(\|q-p_i\|)\phi(q) dq.
\]

Notice that unreliable sensing is expensive and high values of \( \phi(q) \) are also expensive. Summing over all robots, a function representing the overall sensing cost of a given network configuration can be written

\[
\mathcal{H}(P, \mathcal{W}) = \sum_{i=1}^{n} \int_{W_i} f(\|q-p_i\|)\phi(q) dq. \quad (1)
\]

An optimal network configuration corresponds to a particular pair \( (P, \mathcal{W}) \) which minimizes (1).

To solve this minimization problem, we must introduce the notion of a Voronoi partition. The Voronoi region, \( V_i \), of a given robot is the region of points that are closer to that robot than to any other, that is

\[
V_i = \{ q \in Q \mid \|q-p_i\| \leq \|q-p_j\|, \forall j \neq i \}.
\]

The division of an area into such regions is called a Voronoi partition, denoted \( \mathcal{V}(P) \), and is a function of the robot positions. We will use the shorthand

\[
\mathcal{H}(P, \mathcal{V}(P)) = \mathcal{H}(P, \mathcal{V}).
\]

Because the function \( f(x) \) is strictly increasing, the Voronoi partition, \( \mathcal{V} \), minimizes the cost function, \( \mathcal{H} \), for any fixed configuration, \( P \), of robots. This is clear since, for an arbitrary point \( q \in Q \), \( q \in V_i \) gives the smallest value of \( f(\|q-p_i\|) \) over \( i \), and therefore the smallest contribution to \( \mathcal{H} \). Thus we have

\[
\min_{P, \mathcal{V}} \mathcal{H} = \min_{P} \mathcal{H}(P, \mathcal{V}).
\]

To find local minima of \( \mathcal{H}(\mathcal{V}) \), we examine solutions to the expression

\[
\nabla \mathcal{H}(\mathcal{V}) = [\cdots \frac{\partial \mathcal{H}(\mathcal{V})}{\partial p_i} \cdots ]^T = 0.
\]

It is clear that each partial derivative must be zero for a local minimum. Applying a multi-variable generalization of Leibniz Rule, we can move the differentiation inside the integral sign in (1) to get

\[
\frac{\partial \mathcal{H}(\mathcal{V})}{\partial p_i} = \int_{V_i} \frac{\partial f(\|q-p_i\|)}{\partial p_i} \phi(q) dq + \sum_{j \in \mathcal{N}_i} \int_{\partial V_j} f(\|q-p_i\|)\phi(q) \frac{\partial \mathcal{V}_j}{\partial p_i} n_j dq + \int_{\partial V_i} f(\|q-p_i\|)\phi(q) \frac{\partial \mathcal{V}_i}{\partial p_i} n_i dq, \quad (2)
\]

where \( \mathcal{V}_i \) denotes the boundary of the region \( V_i \), \( n_j(q) \) denotes the outward facing normal of \( \partial V_i \), and \( \mathcal{N}_i \) is the set of indices of the neighbors of \( p_i \), excluding \( i \) itself. Note that all the integrals in (2) are \( N \times 1 \) vectors since \( \frac{\partial \mathcal{V}_j}{\partial p_i} \) is an \( N \times N \) matrix and \( n_i \) is an \( N \times 1 \) vector. We assert that the last two terms of (2), in fact, sum to zero. A proof can be outlined as follows. Since \( p_i \) only affects \( \partial V_j \) at the shared boundary of \( V_j \) and \( V_i \), we have that

\[
\sum_{j \in \mathcal{N}_i} \frac{\partial \mathcal{V}_j}{\partial p_i} = \frac{\partial \mathcal{V}_i}{\partial p_i}.
\]

Also, an inward normal, \( -n_i \), for \( V_i \) is equal to an outward normal, \( n_j \), for any of its neighbors \( V_j \), at the boundary which they share. This leads to

\[
\sum_{j \in \mathcal{N}_i} \int_{\partial V_j} f(\|q-p_i\|)\phi(q) \frac{\partial \mathcal{V}_j}{\partial p_i} n_j dq = -\int_{\partial V_i} f(\|q-p_i\|)\phi(q) \frac{\partial \mathcal{V}_i}{\partial p_i} n_i dq.
\]

\(^1\)In contrast, Cortés et al [5] use a probability density function describing the likelihood of an event occurring in a particular area.

\(^2\)This procedure is known in uid mechanics as the Reynolds Transport Theorem.
giving the desired result.

Using this fact, (2) can simply be written
\[
\frac{\partial \mathcal{H}_V}{\partial p_i} = \int_{V_i} \frac{\partial f}{\partial p_i} \phi(q) dq.
\]
We can evaluate the partial derivative of \( f(x) \) using the chain rule, and move \( p_i \) outside of the integral to give
\[
\frac{\partial \mathcal{H}_V}{\partial p_i} = -\int_{V_i} \frac{q}{\|q - p_i\|} \frac{df(x)}{dx} \|q - p_i\| \phi(q) dq + \int_{V_i} \frac{1}{\|q - p_i\|} \phi(q) dq
\]
Next we define two properties analogous to mass-moments of rigid bodies. The mass of \( V_i \) is defined as
\[
M_{V_i} = \int_{V_i} \frac{1}{\|q - p_i\|} \frac{df(x)}{dx} \|q - p_i\| \phi(q) dq,
\]
and the centroid of \( V_i \) is defined as
\[
C_{V_i} = \frac{1}{M_{V_i}} \int_{V_i} \frac{q}{\|q - p_i\|} \frac{df(x)}{dx} \|q - p_i\| \phi(q) dq.
\]
Note that \( f(x) \) strictly increasing and \( \phi(q) \) strictly positive imply both \( M_{V_i} > 0 \ \forall \ V_i \neq \{0\} \) and \( C_{V_i} \in V_i \setminus \partial V_i \) (\( C_{V_i} \) is in the interior of \( V_i \)). Thus \( M_{V_i} \) and \( C_{V_i} \) have properties intrinsic to physical masses and centroids. Substituting these quantities into (3) gives
\[
\frac{\partial \mathcal{H}_V}{\partial p_i} = -M_{V_i} (C_{V_i} - p_i). \tag{6}
\]
Equation (6) implies that local minima of \( \mathcal{H}_V \), and therefore \( \mathcal{H}(P, W) \), correspond to the configurations, \( P \), such that \( p_i = C_{V_i} \ \forall i \), that is, each agent is located at the centroid of its Voronoi region. We will denote the set of all such centroidal Voronoi configurations as \( P_C \). Thus, the optimal coverage task is to drive the group of robots to a centroidal Voronoi configuration, \( P \in P_C \).

III. ESTIMATED ERROR FEEDBACK CONTROL

We will design a control law to take advantage of the surprisingly simple result in (6). The control law will drive the network to an estimated centroid Voronoi configuration using sensory data available to the robots to form an on-line approximation of the centroids of their Voronoi regions.

Assume that the dynamics of each robot can be modeled by the first-order equation
\[
\dot{p}_i = u_i, \tag{7}
\]
where \( u_i \) is the control input. This might mean simply that a low-level controller is in place to enforce first-order dynamics. Next, prescribe the linear proportional control law
\[
u_i = k(C_{V_i} - p_i), \tag{8}\]
where \( C_{V_i} \) is an estimate of \( C_{V_i} \) based on the information available to robot \( i \). To investigate the stability of such a control law we propose to use \( \mathcal{H}_V(P) \) as a Lyapunov-like function. Taking the time derivative of \( \mathcal{H}_V(P) \) along the trajectories of (7) gives
\[
\dot{\mathcal{H}}_V = \sum_i \frac{\partial \mathcal{H}_V}{\partial p_i} \dot{p}_i,
\]
and using (6) and (8) we get
\[
\dot{\mathcal{H}}_V = -k \sum_{i=1}^{n} M_{V_i} e_i^T e_i, \tag{9}
\]
where \( e_i = (C_{V_i} - p_i) \), and \( \dot{e}_i = (\dot{C}_{V_i} - p_i) \). The actual error, \( e_i \), is unknown. Notice, however, that if an estimate, \( \hat{e}_i \), can be found such that the inner product of the two errors is positive, convergence of \( \hat{e}_i \) to zero will be guaranteed. Geometrically, this means that the angle between \( \hat{e}_i \) and \( e_i \) must remain less than \( \pi/2 \) rad for all time. We use this insight to design a centroid estimate, \( \hat{C}_{V_i} \), using only sensed information local to robot \( i \).

Henceforth we will deal with the specific case in which \( f(x) = 1/2x^2 \). This causes the factor
\[
\int_{V_i} \frac{1}{\|q - p_i\|} \frac{df(x)}{dx} \|q - p_i\| \phi(q) dq
\]
to become unity, making the proceeding expressions more transparent. The method presented, however, is valid for any strictly increasing \( f(x) \) with smooth first derivatives.

A. Control Using Linear Approximations

Consider a situation in which the values of the sensory function, \( \phi(p_i) \), and its gradient, \( \nabla \phi \mid_{p_i} \), are available continuously to robot \( i \) at its current position. In this case, the available information motivates a linear estimate of \( C_{V_i} \) over the known region \( V_i \). We define the linear approximation to \( C_{V_i} \) calculated from an agent at position \( p_i \) as
\[
\hat{C}_{V_i} = \frac{1}{M_{V_i}} \int_{V_i^+} q\hat{\phi}_i(q) dq, \tag{10}
\]
where
\[
\hat{M}_{V_i} = \int_{V_i^+} \hat{\phi}_i(q) dq, \tag{11}
\]
\[
V_i^+ = V_i \cap \{ q \mid \hat{\phi}_i(q) \geq 0 \}, \tag{12}
\]
\[
\hat{\phi}_i(q) = \phi(p_i) + \nabla \phi^T \mid_{p_i} (q - p_i). \tag{13}
\]

The above formulation follows naturally from the definition of \( C_{V_i} \) and \( M_{V_i} \) in (5) and (4). The integrals are taken over \( V_i^+ \) to avoid calculating values of \( \hat{M}_{V_i} \leq 0 \) and values of \( \hat{C}_{V_i} \) outside of the region \( V_i \).

We can prove the stability of the proposed controller in the case of linear \( \phi(q) \). In this case the function \( \phi(q) \) is fully parameterized by its value and gradient as measured at any point, therefore \( \hat{\phi}_i(q) = \phi(q) \). This special case becomes mathematically equivalent to that treated in [5]. Then \( \hat{C}_{V_i} = C_{V_i} \) and from (9) we have that
\[
\dot{\mathcal{H}}_V = -k \sum_{i=1}^{n} M_{V_i} e_i^T e_i.
\]
As was noted previously, \( M_{i\ell} > 0 \), therefore \( \mathcal{H}_V \leq 0 \forall p_i \), and \( \mathcal{H}_V = 0 \text{ iff } p_i = C_{i\ell} \forall i \). Additionally, \( P_C \) is the largest invariant set since, from (7) and (8), \( p_i = 0 \ \forall i \in P \). Then by LaSalle’s theorem \( \lim_{t \to \infty} p_i = C_{i\ell} \forall i \) which implies \( P \to P_C \).

In the case of nonlinear \( \phi(q) \), we observe that the control law with a linear estimation causes the robots to converge to the estimated centroid, \( \hat{C}_V \), of their Voronoi region. We call such configurations near-optimal. It is difficult to bound the error between the estimated centroid and the actual centroid in the general \( N \)-dimensional case above. It is however possible to do so for 1-dimensional systems, where robots can move along an arbitrary curvilinear segment in three-space (e.g. a robot moving along a track.)

**B. Efficient Computation of Integrals**

We will use the convenient form of the centroid estimation above to derive an analytical solution to the centroid integral. The analytical expression will make the control law feasible for robot platforms with limited computational resources. This eliminates the need to discretize the Voronoi region and approximate the \( M_{i\ell} \) and \( \hat{C}_V \) integrals in a computationally-expensive numerical procedure.

Since the estimated \( \hat{\phi} \) is polynomial in \( q \), we can use the results from [3] to find the integrals for \( \hat{M}_{i\ell} \) and \( \hat{C}_V \), as polynomials in the vertices of the Voronoi region \( V_i \). First, from (10), (11), and (13) we can divide the integral expression for \( \hat{C}_V \) and \( \hat{M}_{i\ell} \) into monomial components to get

\[
\hat{C}_V = \frac{1}{\hat{M}_{i\ell}} \left( \phi(p_i) - \nabla \phi^T | p_i, p_i \right) \int_{V_i^+} q dq + \frac{1}{\hat{M}_{i\ell}} \int_{V_i^+} q^T dq \nabla \phi | p_i, \quad (14)
\]

where

\[
\hat{M}_{i\ell} = \left( \phi(p_i) - \nabla \phi^T | p_i, p_i \right) \int_{V_i^+} dq + \nabla \phi^T | p_i, p_i \int_{V_i^+} q dq. \quad (15)
\]

These expressions can be simplified further by introducing the constants \( c_1 = \left( \phi(p_i) - \nabla \phi^T | p_i, p_i \right) \) and \( \left[ c_1 c_2 \right]^T = \nabla \phi | p_i \), and by defining a general integral of a monomial over a polygon as

\[
T_{V_i^+}^{\alpha\beta} = \iint_{V_i^+} x^\alpha y^\beta dxdy, \quad (16)
\]

where \( q = [x \ y]^T \). Then we can write (14) and (15) as

\[
\hat{C}_V = \frac{c_1}{\hat{M}_{i\ell}} \left[ T_{V_i^+}^{10} \ T_{V_i^+}^{11} \right] + \frac{1}{\hat{M}_{i\ell}} \left[ T_{V_i^+}^{20} \ T_{V_i^+}^{21} \right] \left[ \begin{array}{c} c_2 \\ c_3 \end{array} \right], \quad (17)
\]

where

\[
\hat{M}_{i\ell} = T_{V_i^+}^{00} c_1 + \left[ T_{V_i^+}^{10} \ T_{V_i^+}^{11} \right] \left[ \begin{array}{c} c_2 \\ c_3 \end{array} \right]. \quad (18)
\]

The solution of the integral in (16) is given in analytical form by equation (4) from [3]. The cases specifically required for the computation of (17) are simplified and enumerated below:

\[
T_{V_i^+}^{00} = \frac{1}{2} \sum_{i=1}^{m} (y_{i+1} - y_i)(x_{i+1} + x_i),
\]

\[
T_{V_i^+}^{01} = \frac{1}{6} \sum_{i=1}^{m} [(x_i - x_{i+1})y_{i+1}^2 + y_{i+1}y_i + y_i^2] + 3(x_{i+1}y_{i+1}^2 - x_iy_i^2),
\]

\[
T_{V_i^+}^{10} = \frac{1}{6} \sum_{i=1}^{m} (y_{i+1} - y_i)(x_{i+1}^2 + x_{i+1}x_i + x_i^2),
\]

\[
T_{V_i^+}^{11} = \frac{1}{24} \sum_{i=1}^{m} [(y_{i+1} - y_i)(2x_{i+1}x_i(y_{i+1} + y_i) + x_{i+1}^2(3y_{i+1} + y_i) + x_i^2(y_{i+1} + 3y_i)),
\]

\[
T_{V_i^+}^{20} = \frac{1}{12} \sum_{i=1}^{m} [(x_i - x_{i+1})y_{i+1}^2 + y_{i+1}y_i + y_i^2] + 4(x_{i+1}y_{i+1}^2 - x_iy_i^2),
\]

\[
T_{V_i^+}^{20} = \frac{1}{12} \sum_{i=1}^{m} (y_{i+1} - y_i)(x_{i+1}^2 + x_{i+1}^2 + x_i^2),
\]

where \( m \) is the number of vertices, \([x_i \ y_i]^T\), of \( V_i^+ \), and where the index \( m + 1 \) is interpreted as 1. The vertices must be ordered counter-clockwise around the perimeter of \( V_i^+ \).

The expression in (17) with the associated expressions for the integral terms can be computed directly to give the actual value of \( \hat{C}_V \) and \( \hat{M}_{i\ell} \).

**C. Practical Algorithms**

A practical method for implementing the proposed control law on a network of robots is detailed in Algorithm 1. We assume that the robots have access to a procedure for obtaining their own Voronoi region. Several such algorithms exist, for example those given in [5], [6]. In our hardware implementation, we use the Delaunay computation from [7] and build Voronoi regions using knowledge of the Delaunay neighbors.

This algorithm is decentralized, fully distributed, and requires minimal communication between neighboring robots. It can be used on teams of large robots, on teams of small robots such as [8], or on mobile sensor network nodes with limited computation and storage capabilities such as the mobile Mica Motes described by [10].

**IV. NUMERICAL SIMULATIONS**

A. Implementation

Simulations were carried out in a Matlab environment. The dynamics in (7) with the control law in (8) for a group of robots were modeled as a system of coupled differential equations. Voronoi computation was carried out in a centralized fashion using standard Matlab Voronoi functions. The centroid was calculated using the analytical solution to the centroid...

integral given in (17). A custom, fixed-time-step numerical solver was used to integrate the equations of motion of the group of robots. The sensory function, φ(q), was built from Gaussians. Specifically, two cases were investigated. For the first case, the function was chosen as

\[ φ(q) = \frac{γ}{σ\sqrt{2π}} \left( e^{-\frac{(q-x_1)^2}{2σ^2}} + e^{-\frac{(q-x_2)^2}{2σ^2}} \right). \]  

A function with multiple maxima was used to illustrate the robustness of the control scheme to complicated sensing environments. For the second case, a single Gaussian was used of the form

\[ φ(q) = \frac{γ}{σ\sqrt{2π}} e^{-\frac{(q-x)^2}{2σ^2}}. \]

This φ(q) was chosen to gather statistical data about convergence properties over a number of runs. The parameters used for the Gaussian functions were γ = 1, σ = 1/√2, μ_1 = (.2, .2), and μ_2 = (.8, .8). The control gain was k = 5, the region Q was set to be a square of 1 meter on each side, and q was a Cartesian point [ x y ]^T ∈ Q.

B. Results

Figure 2 shows the results of a typical simulation run with the φ(q) given by (19). The initial configuration of the network is shown in Figure 2(a), the trajectories of the agents (dashed lines) in Figure 2(b), and the final configuration in Figure 2(c). The centers of the Gaussian functions, μ_1 and μ_2, are marked with x’s. In Figure 2(d), the time evolution of the x and y coordinates of one agent are shown.

To assess convergence properties of the algorithm, statistical results were compiled over a number of simulation runs with random initial configurations using the φ(q) given by (20). Three batch runs were executed: one batch of 1000 simulation runs with 10 robots, one of 100 simulation runs with 100 robots, and one of 10 simulation runs with 1000 robots. Each simulation run was said to converge if the mean normed error of the group of robots was found to be less than 1 x 10^-7 m. The mean and standard deviations of the convergence times are shown in Table I.

The mean normed errors are shown in Figure 3 for all simulation runs for each of the three batches. The plots are given on semi-log axes to emphasize that after some time, the convergence rate of the closed-loop system appears to be nearly exponential.

It is interesting to note that, although coverage rates decrease as the network size increases, the time to reach a particular small error value does not necessarily increase, as shown in Table I. One can interpret this effect as the result of two opposing factors. With few robots, global movement of the network can occur rapidly because the motion of one robot quickly propagates to influence all of the others. This propagation effect becomes more sluggish as the network size increases. However, with a large number of robots, there is a high likelihood that the initial position of any one robot is close to its final position. Thus each robot has less distance to cover. The push-and-pull of these two factors creates the effect that is evidenced in the data. Notice also that the variance appears to decrease with increasing network size. This is a statistical side-effect. Because the plots show mean normed error, a large network will be more likely to have a mean

close to the ensemble mean than a small network.

The final distribution of the robots with respect to distance from the Gaussian center is shown for all three batches in Figure (4). The densities appear more jagged for smaller networks because there are fewer centroidal Voronoi configurations for smaller groups of robots. The densities are not precisely Gaussian, nor are they meant to be. But there are high concentrations of robots where the $\phi(q)$ is large, indicating an area of sensory interest, and low concentrations where $\phi(q)$ is small, where there is little sensory interest.

V. HARDWARE EXPERIMENTS

We implemented and tested the algorithm on a group of mobile “SwarmBots.” A light source was used to create a sensory function $\phi(q)$ of light intensity. The robots used readings from light sensors and neighbor localization to carry out Algorithm 1.

A. The Swarm Hardware

Each SwarmBot (Figure 5) is autonomous and is equipped with bump sensors, light sensors, and an infra-red inter-robot communication and localization system called ISIS. The light sensors detect the sensory input. The ISIS inter-robot localization system provides local neighbor positions used to compute the Voronoi cells.

We limited the range of the localization system to one meter to increase the diameter of the network and minimize the number of inter-robot packet collisions. This algorithm uses no communications other than the localization messages, allowing us to test it with many robots in a small physical space.

B. Implementation of the Control Algorithm

The implementation of Algorithm 1 on the SwarmBot system required several modifications. The robots had a limited communication range of radius one meter, therefore the Delaunay neighbors computed by any robot were only those Delaunay neighbors within the one meter disk of the robot. These local Delaunay graphs might not be the same as their global counterparts. We assumed that edges of greater than length one meter are uncommon in the triangulated graphs we consider and the effects of removing them have little impact.
On The Edge

To overcome this problem, we fixed the magnitude of the distance. This was not enough information to compute the signal strength, estimated centroid value.

Fig. 6. The method used for closing the unbounded Voronoi region of a robot with 1 neighbor is shown on the left. The method for an unbounded Voronoi region of a robot with any two consecutive neighbors separated by more than \( \pi \) rad is shown on the right.

In addition, Algorithm 1 requires that each robot can detect and localize the boundaries of the region \( Q \). This is necessary to prevent the Voronoi region of any robot from being unbounded. We did not implement boundary sensing on the SwarmBot. Instead, we developed three heuristic rules for truncating infinite Voronoi regions. Unbounded Voronoi regions occur in three distinct cases for robots on the boundary of the network. These are enumerated below along with the associated truncation technique.

1) No Voronoi Neighbors: The centroid is computed to be the robot’s current position, thus the robot does not move until it acquires a neighbor.

2) One Voronoi Neighbor: A Voronoi region is constructed from an isosceles triangle of constant size whose base lies on the bisector between the two robots (see the left of Figure 6).

3) Two Consecutive Voronoi Neighbors Separated by an angle \( \geq \pi \): A line is added perpendicular to the bisector of the infinite region at a constant distance from the robot (see the right of Figure 6). The two intersection points of this line with the unbounded Voronoi region are taken as vertices of the truncated Voronoi region.

Also, the robots’ light sensors returned a bearing and distance. This was not enough information to compute \( \nabla \phi \big|_{p_i} \), directly. To overcome this problem, we fixed the magnitude of \( \nabla \phi \big|_{p_i} \) and determined its direction from the sensory stimulus. The signal strength \( \phi(p_i) \) was measured directly.

Finally, the SwarmBot had a low-level controller in place which allowed the robot to move to a particular point relative to its current position. We used this position control as a substitute for velocity control. In particular, at each time instant, the input to the position controller was given as the estimated centroid value \( \hat{C}_V \). This turned out not to be a difficult since the low level control-loop was already well suited for the experiments.

The computational and memory requirements for this algorithm were small, and modification of the algorithm to run with integer calculations was straightforward. On the 40MHz ARM Thumb processors used in the SwarmBots, the memory usage for all the steps outlined in Algorithm 1, including the special cases discussed above, was 3949 bytes of code and 1284 bytes of RAM. With 8 neighbors, one cycle of the algorithm ran at 70ms, fast enough for real-time position updates.

C. Experiments

We measured the performance of the algorithm in two sets of experiments. For the first set of experiments, a factor was introduced to change the robots’ final configuration. In particular, if we define \( \phi(p_i) \) as the light intensity measured by the robots’ light sensors at \( p_i \), we chose a DC offset, \( \Phi_{offset} \) to create a \( \phi \) function \( \phi = \Phi_{offset} + \hat{\phi} \). This had the effect of reducing the influence of the measured light gradient. Thus, final robot density varied inversely with the value of \( \Phi_{offset} \). Three runs were performed for each of six values of \( \Phi_{offset} = \{800, 400, 200, 100, 50, 10\} \). In each experimental run, 40-50 robots were started uniformly dispersed in a dark, \( 8' \times 8' \) workspace. A light source was placed at the middle of one of the perimeter walls of the workspace. The robots were given two minutes to reach a final configuration. Photographs of the final robot configurations are shown for each \( \Phi_{offset} \) value in Figure 7, along with plots of the final robot densities as a function of distance from the light source.

A second set of experiments was carried out to quantify the actual error of the robots over the course of a single run. Twenty robots were started concentrated in one corner of the \( 8' \times 8' \) workspace. The light intensity was controlled to be as uniform as possible over the workspace. Special stationary robots were evenly spaced along the perimeter of the workspace, five along each wall. These were used to help ensure that the voronoi regions of the active robots remained bounded throughout the experiment without having to use the heuristics described above. The 20 active robots ran algorithm 1 for a total of 3 minutes. They were stopped at regular time intervals throughout the 3 minutes, and their positions were measured. The position measurements were used to compute, off line, the error between each robot’s position and the centroid of its Voronoi region. The time history of the mean error measured in this way is shown in Figure 9. Note that the error diminishes over time as would be expected.

VI. Conclusion

In this paper, a decentralized method for controlling coverage in mobile sensor networks was presented. The method is related to one proposed in [5], and introduces an innovation that allows for the network to adapt to unknown sensory environments. An analytical expression for centroid calculations was derived to make the algorithm computationally feasible on small robot platforms. The control scheme was demonstrated in numerical simulation. The control scheme

---

3A Voronoi based control scheme with limited range communication was shown in [4] to have similar convergence properties as the case with unlimited communication range.
The upper row of images show the final positions of 40 robots using the proposed control law. The sensor offset, $\Phi$, is labeled above each picture. The graph below each image plots the normalized density of the robots as a function of their radius from the light source. A uniform density would appear as a horizontal line with a value of one.

The graph below each image plots the normalized density of the robots as a function of their radius from the light source. A uniform density would appear as a horizontal line with a value of one.

The initial configuration and the final configuration for an experiment with 50 robots is shown.

Fig. 8. The initial and final configurations for an experiment with 50 robots is shown.

The mean error between the robots’ positions and the centroids of their Voronoi regions is shown as a function of time for an experiment with 20 robots. Because of sensor noise, we used a fixed error threshold of 0.075 m. Robots with desired positions within this distance remained stationary, limiting the convergence of the mean error.

Because of sensor noise, we used a fixed error threshold of 0.075 m. Robots with desired positions within this distance remained stationary, limiting the convergence of the mean error.

was also implemented on a SwarmBot platform using integer calculations in a lean computing environment. The ability to implement the control scheme on such a platform emphasizes its practicality and minimalist nature. Robust performance was demonstrated in a number of experimental trials.

Potential extensions to this control method are numerous. For example, the approach in this work used minimal communication among robots, only requiring localization to produce a Voronoi partition. Shared estimates of the sensory function are possible if more communication overhead is allowed. For example, each robot might estimate the sensory function from a quadratic fit of its own and each of its Voronoi neighbors’ measured values of $\phi(q)$. Theoretical, numerical, and experimental studies of this and other methods are ongoing.
